# Introduction

---

Yelp is one of the most popular search engines in restaurants that users can get lots of helpful information at a glance containing the store's location; opening hours; menus with prices and actual customers' reviews; pictures; ratings. A few times, I found that some restaurants, which keep over 4.5 ratings placed on top of the results page, were not the best selections and I wondered which factors of the restaurant proceed Yelp to optimize in the search results page. The objective of the project is to examine which factors from restaurants determine their rankings in the search result page.

## Yelp Ranking Factors

According to the Local Visibility System, on Yelp's search result page, there are some major factors lead the ranking of the businesses listed on the top (Yelp Ranking Factors). To find the factors that determine the Yelp ranking, the report applied several prominent variables from the list below.

1. Existence of reviews.
2. Keyword-relevance of reviews.
3. Business categories specified.
4. Name of business.
5. A number of reviews.
6. Reviews by "Elite" members.

7. Check-ins via smartphone.
8. Ratings of reviewers.

Some of them are located on the content page - 2, 6, 7, and others are not the numeric values and impossible to track the information - 3, 4. The report was selected number of reviews - 1, 5 and prices which are both located in results page. The prices were not the major factors defining by the Local Visibility System, but the report expected and wanted to find some good findings on prices. Since the result page only contains 30 restaurants in the first view, the report select three different cities to gather information for the diversity and broader volumes.

Also, the local brand management service Charmeter assumed that the content page needs to work by adding more photos (free), managing the specialties section with a good description (free), applying the call to action button (paid), offering customers check-in (free) to get more customers attention. These were needed to web scraping from each page, so in this case, fetching the API or downloading existing JSON, or CSV files would be more fit rather than applying web scraping method per each page.

## **Hypothesis**

A higher ranking will take a large number of reviews. Or a higher ranking has less expensive menus. There needs to be a linear relationship between the two variables, “the number of reviews ” and “ranking” or “prices” and “ranking”.

## Methodology

---

Since Yelp doesn't offer any official API to the public - only offers to businesses or valid JSON datasets<sup>1</sup>, there is a great Python library for web scraping to gather raw information online, BeautifulSoup (figure. 1). To conduct an accurate ranking on the search results page, the main end-point page [https://www.yelp.com/search?cflt=restaurants&find\\_loc=nyc](https://www.yelp.com/search?cflt=restaurants&find_loc=nyc) was picked because the ranking system on this page was not influenced by the distance between stores and the location of the device itself. Later on, San Francisco and Chicago were also managed to see the analytics on NYC dataset is accurate.

```
from splinter import Browser
from bs4 import BeautifulSoup
import os
import pandas as pd
from datetime import datetime
import platform
import matplotlib.pyplot as plt
```

Figure. 1: Imports the libraries for scraping data online.

### Web Scraping to collect datasets

For this project, the report proceeded to conduct analytics on the Yelp search result page that holds a number of reviews and prices. These two major variables were selected to analyze the relationship to the Yelp ranking. The prices were displayed by a dollar sign, not a numeric value, and both numbers of reviews and prices stood out on the result page. There was able to capture other information about the restaurants so the report also scrapped their address, names, and types of restaurants.

---

<sup>1</sup> There is an existing JSON file offering non-officially, but the dataset is so huge and enables to convert to CSV file to be a readable dataset (<https://www.yelp.com/dataset>).

```

def init_browser():

    datas = scrape(browser, url)
    return datas

```

Figure. 2 : The yellow line points out five functions to scrape Yelp data.

To scrap any information of Yelp on Jupyter notebook, the report wrote functionalized codes and run the final function **def main()** to call other functions simultaneously (Figure. 2). Since

Jupyter notebook doesn't work well with direct scraping by beautiful soup, Codes for opening the new Chrome window was a priority which refers to `def init_browser()`. Then, a new window opened with given URL from `def get_html(browser, url)` and returned the dataset in Html (Find the `<tag>` divs or spans, a, p, address with class names) and stored them into a dictionary using beautiful soup library by `def get_data(html)`. To handle both browsing URL function and get stored data function at once, `def scrape(browser, url)` were call the two functions `get_html(browser, url)` and `get_data(html)`.

The `Get_data` function collected actual scraping information of Yelp by pointing out their tag and class name of the restaurants' ranking; name; rating; a number of reviews; average price; address; neighborhood; types and stored them into a new dictionary. After calling the final `main()` function, a data frame was created and called them using the panda's library<sup>2</sup> (Figure. 3).

```
main()
df = pd.DataFrame(data).T
df.head()
```

	title	rating	num_review	price	types	address	neighbourhood	time
1	Amélie	4.5	1	\$\$	[French, Wine Bars]	22 W 8th St	Greenwich Village	2019-10-25 21:20:23.057085
2	Upstate	4.5	2593	\$\$	[Seafood, Wine Bars, Beer Bar]	95 1st Ave	East Village	2019-10-25 21:20:23.057085
3	LoveMama	4.5	1796	\$\$	[Thai, Malaysian, Vietnamese]	174 2nd Ave	East Village	2019-10-25 21:20:23.057085

Figure. 3 : The dataset transfer to data frame from the panda's library.

<sup>2</sup> It offers data structures and operations for manipulating numerical tables and time series (Wikipedia).

## Cleaning Data

### Check data types of the data frame

```
df.dtypes

ranking          object
title            object
rating           object
num_review       object
price            object
address          object
neighbourhood    object
time            datetime64[ns]
type_1           object
type_2           object
type_3           object
dtype: object
```

### Change numeric values to be a int or float

```
df['ranking'] = df['ranking'].astype(int)
df['rating'] = df['rating'].astype(float)
df['num_review'] = df['num_review'].astype(int)
```

Figure. 4 : Check data types and use default function to change the types of variables at ease.

Since a data frame has lots of variables with both numeric and string values, the report checked each variable's types of the data frame (Figure. 4). Two variables of price and types which were needed to change - a price column had to transfer to numeric values and a types column contained listed multiple strings that were necessary to change to multiple columns with each string value (Figure. 5).

### Make the multiple columns with string value from a column with list value

- [types] -> 'type\_1', 'type\_2', 'type\_3'
- Drop the column [types]
- Make a ranking column from index

```
df2 = pd.DataFrame(df['types'].values.tolist())
df = df.assign(**{'type_1': df2[0].values, 'type_2': df2[1].values, 'type_3': df2[2].values})
df = df.drop(['types'], axis=1)
df = df.reset_index()
df = df.rename(columns = {'index': 'ranking'})
df.head()
```

	ranking	title	rating	num_review	price	address	neighbourhood	time	type_1	type_2	type_3
0	1	Amélie	4.5	1	\$\$	22 W 8th St	Greenwich Village	2019-10-25 21:20:23.057085	French	Wine Bars	None
1	2	Upstate	4.5	2593	\$\$	95 1st Ave	East Village	2019-10-25 21:20:23.057085	Seafood	Wine Bars	Beer Bar
2	3	LoveMama	4.5	1796	\$\$	174 2nd Ave	East Village	2019-10-25 21:20:23.057085	Thai	Malaysian	Vietnamese
3	4	Burger & Lobster	4	4647	\$\$	39 W 19th St	Flatiron	2019-10-25 21:20:23.057085	Seafood	Burgers	American (New)
4	5	Thai Villa	4.5	5298	\$\$	5 E 19th St	Flatiron	2019-10-25 21:20:23.057085	Thai	Asian Fusion	None

Figure. 5 : A listed multiple strings in a column transferred to three columns with one string.

## Applying the linear model in R Studio

The report stated the hypothesis that a higher ranking will take a large number of reviews. To make a linear model with the ny data, use num\_review column to be a dependent variable and ranking is the independent variable (Figure.6 - 1). To predict the number of reviews on the highest ranking, use data.frame("ranking" = 1) and predict it within the linear model ny data (Figure.6 - 2). Then, use ggplot to plot the predicted values with actual values (Figure.6 - 3).

```

15 ## 1 --- Using raw_ny dataset, pick a variable "num_review" --- ##
16 ny <- raw_ny[, c(1, 3, 4, 5)]
17 glimpse(ny)
18
19 1 lm_ny <- lm(num_review ~ ranking, data=ny)
20 summary(lm_ny)
21
22 fitted_ny <- fitted.values(lm_ny)
23 fitted_ny
24 residuals_ny <- residuals(lm_ny)
25 residuals_ny
26
27 lm_matrix_ny <- broom::augment(lm_ny)
28 head(lm_matrix_ny)
29 lm_matrix_ny$.resid_abs <- abs(lm_matrix_ny$.resid)
30 lm_matrix_ny %>% arrange(desc(.resid_abs)) %>% head()
31
32 2 new_ny <- data.frame("ranking" = 1)
33 new_ny
34 predict(lm_ny, newdata=new_ny)
35
36 myny <- broom::augment(lm_ny, newdata = new_ny)
37 myny
38
39 3 ggplot(data=ny, aes(x=ranking, y=num_review)) + geom_point() +
40   geom_smooth(method = 'lm') + geom_point(data=myny, aes(y=.fitted), size = 3, color = 'red') +
41   labs(title='Num_review by Ranking with predict model')
42
43 ggpairs(data = ny, columns = 1:4)
44 cor(ny$ranking, ny$num_review)
45

```

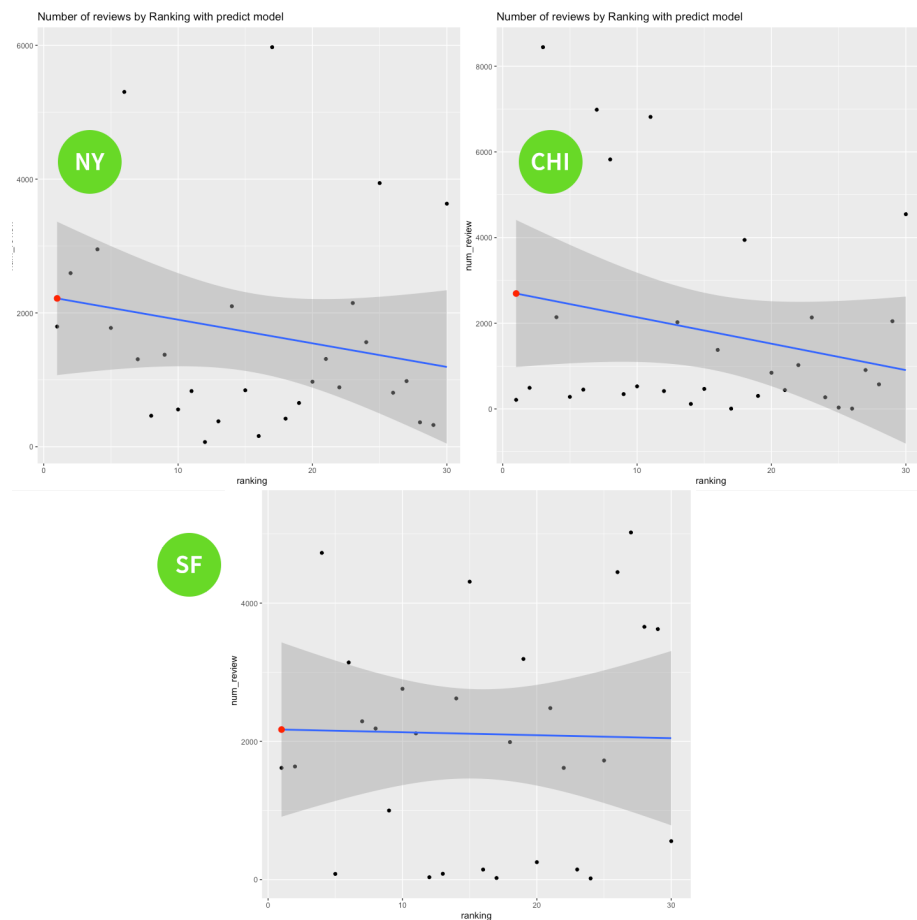

Figure. 6

# Findings

---

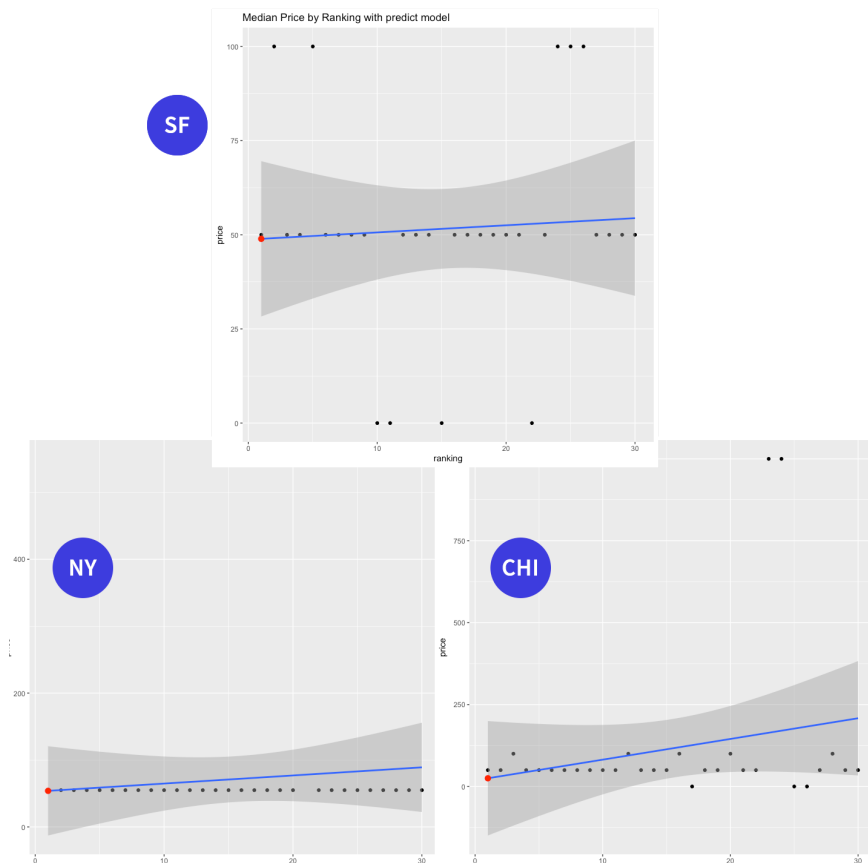

**A higher ranking has a larger number of reviews, but San Francisco has an aspect of nonlinear regression.**

- New York and Chicago data has a cor-relationship between num\_reviews and ranking but are not too dense nor strong. The Yelp ranking's influence in the number of reviews is clearly evident in the Chicago chart. The higher ranking (x-axis) takes higher number of reviews (y-axis).
- Unlikely, San Francisco spread with a wide number of reviews and don't have correlation between ranking and number of reviews. The trend line is only a straight line and seems that most of the data points don't follow the trend.

## A higher ranking has moderately less expensive menus.

- Since I use a price variable to capture only the median price of the menu, all three cities' data points take restricted range of the price (y-axis).
- Correlation between ranking (x-axis) and prices (y-axis) are moderate and dense.
- Some Highest median prices are placed in throughout the overall ranking, so it means the price is not the prior factor to predict the Yelp ranking.
- San Francisco takes place in higher average median prices compared with other cities.

## Conclusion

---

Overall linear regression charts between “number of reviews” and “ranking”, or “prices” and “ranking” didn’t show a strong and dense relationship, they are in a linear regression relationship. However, the fitted points from linear model doesn’t seem to capture an accurate prediction which has huge residual values up to more than 5,700 on number of reviews.

There was also some limitation of the dataset since the report only scrape information in the results page with only 30 restaurants per city. The further studies on Yelp ranking will be needed with more volumes in each dataset and to gather information on the content page as well. In addition to this, comparing multiple variables might be required, through these variables, such as a number of photos; the existence of the “Elite” reviewer; the existence of the check-in feature for mobile users, prediction of the Yelp ranking will make more sense.

# Appendices

## Appendix 1: Scraping data on Yelp using BeautifulSoup on Jupyter notebook

### Import the Libraries
